KEYWORDS: artificial enzymes, copper catalysis, superoxide dismutase, catalase, antioxidant catalysis

# ■ **INTRODUCTION**

 $O<sub>2</sub>$  multiredox chemistry is essential for aerobic life. On the other hand, processing of  $O_2$  via multielectron transfer is also associated with the release of toxic radical species. These are generally defined as reactive oxygen species (ROS) and include the superoxide anion  $(O_2^{\bullet -})$ , hydrogen peroxide  $(H_2O_2)$ , and the hydroxyl radical species (HO•). At the cellular level, ROSspecific enzymes provide the natural defense against this oxidative risk. The antioxidant frontline stems from the combined action of superoxide dismutase (Cu−Zn, Mn, Fe, Ni-dependent SOD), catalase (Fe, Mn-dependent catalase  $(CAT)$ ), and glutathione peroxidase  $(GSX)$ .<sup>[1](#page-8-0),[2](#page-8-0)</sup> ROS detoxification occurs via a cascade catalysis initiated by SOD via  $\mathrm{O}_2^{\bullet-}$ dismutation to  $O_2$  and  $H_2O_2$ , and terminated by CAT/GSH using hydrogen peroxide as the primary substrate. This enzymatic domino effect is instrumental to prevent  $H_2O_2$ accumulation and the insurgence of branching radical chains, Haber−Weiss chemistry, responsible for an exponential increase of the oxidative risk.<sup>[1](#page-8-0),[2](#page-8-0)</sup> Indeed, biorelevant metal ions, like Fe(II/III) or  $Cu(I/II)$ , have been recently investigated in terms of their double-faceted antioxidant effect or toxicity as the two sides of the same coin. In particular the multisite binding modes and equilibria of copper ions at protein sites are being investigated with regard to cellular toxicity and disease pathogenesis.<sup>[3](#page-8-0)</sup> Therefore, a new route can be traced by evaluating the Cu-induced risk based on the stereoelectronic features of copper sites that regulate the Curedox manifold and its response toward ROS generation/ neutralization.<sup>[3](#page-8-0)</sup>

In this respect, the natural copper−zinc superoxide dismutase (Cu−ZnSOD) shows a heterobimetallic active site, with a penta-coordinated Cu<sup>II</sup> center ligated by four His residues and one water molecule with a distorted square pyramidal coordination geometry. During SOD turnover, the redox-active copper center cycles between the  $Cu^{II/I}$  oxidation states upon interaction with  $O_2^{\bullet-}$  (eqs 1 and 2), while zinc appears to play a role in the overall folding stability and in facilitating a broader  $pH$  independence.<sup>4</sup>

$$
O_2^{\bullet-} + Cu^{II} - Zn^{II}SOD \rightarrow O_2 + Cu^{I} - Zn^{II}SOD
$$

$$
O_2^{\bullet-} + 2H^+ + Cu^{\text{I}} - Zn^{\text{II}}SOD \rightarrow H_2O_2 + Cu^{\text{II}} - Zn^{\text{II}}SOD
$$
  
(2)

Due to the rich oxygen chemistry known for copper complexes, reduction to  $Cu(I)$  offers competing radical mechanisms by intercepting oxygen (eqs 3 and 4) and/or by single electron transfer to  $H_2O_2$ .

## <span id="page-1-0"></span>Table 1. Catalytic Copper Antioxidants Featuring SOD and CAT Activity in Water<sup>a</sup>

 ${}^a$ Ligand abbreviations are as follows: TAAP = obtained by self-condensation of 5-amino-3-methyl-l- phenylpyrazole-4-carbaldehyde (AMPC) in the presence of copper(II); HPBMPA = N-propanoate-N,N-bis(2-pyridylmethyl)amine; Cyss = cystine; apz-pn = N,N′-bis(2-acetylpyrazyl)methylene-<br>1,3-diaminopropane. <sup>b</sup>E<sub>1/2</sub> is measured in 0.05 M phosphate buffer, pH 7.8, 0.1 M anions are generated by the xanthine/xanthine oxidase system (40  $\mu$ M xanthine, 0.0053 U mL<sup>-1</sup> xanthine oxidase, 10  $\mu$ M cyt c, catalase 15  $\mu$ g  $mL^{-1}$ , 50 mM phosphate buffer, pH = 7.80). IC<sub>50</sub> indicates the catalyst concentration required to attain 50% inhibition of the cyt c reduction; log  $k_{cat}(O_2^{\bullet-})$  refers to the rate constant of catalytic superoxide dismutation; estimated errors are within  $\pm 10\%$ . <sup>d</sup>CAT activity is based on oxygen evolution kinetics, monitored by a pressure transducer.  $R_{\text{max}}$  were obtained by linear regression of data within 10%  $H_2O_2$  conversion; the estimated errors are within  $\pm 10\%$ .  $k_{\text{H}_2\text{O}_2}$  obtained by linear regression of pseudo-first-order rate constants  $k_{\text{obs}} = k_{\text{H}_2\text{O}_2}[\text{H}_2\text{O}_2]$ . <sup>e</sup>nd = not determined.  $^f$ Measured in 50 mM BBS, pH 7.8 at 25 °C. <sup>g</sup>Measured in 50 mM KH buffer, pH 7.4 at 25 °C. <sup>h</sup>SOD activity is measured by NBT assay. <sup>i</sup>CAT activity is based on oxygen evolution kinetics, monitored by a reverse buret. <sup>j</sup>CAT activity is based on oxygen evolution kinetics, monitored by Warburg apparatus.

<sup>a</sup>For clarity, counter ions and solvent molecules which are not part of the Cu coordination spheres have been omitted.

The final outcome is the paradox of the enhanced toxicity registered within brain tissues when the isolated Cu−ZnSOD (bovine protein) is administered as antioxidant under anoxia/ reoxygenation conditions.<sup>6</sup> This example highlights the crucial issue of designing a multilevel catalytic manifold that goes beyond a specific ROS target and works for the simultaneous neutralization of ROS cascades. We have recently reported on a Mn-based synthetic "di-zyme" behaving as the artificial SOD/CAT conjugate with the highest activity reported up to date for a Mn catalyst. $\frac{7}{1}$  $\frac{7}{1}$  $\frac{7}{1}$  In the case of copper species, the majority of SOD-mimetics display a mononuclear  $Cu(II)$ center and generally fail to provide a bielectronic mechanism for  $H_2O_2$  dismutation.<sup>[8,](#page-8-0)[9](#page-9-0)</sup> Few single-site Cu(II)-complexes are reported to exhibit a dual SOD/CAT-like activity, while they

were found to promote single-electron transfer mechanisms with the formation of harmful radical species  $(Table 1)$ .<sup>[10](#page-9-0)</sup> Dinuclear copper complexes, mimicking the structural motif of the manganese catalase, are known; however, their CAT-like activity has been reported only in organic solvents, lacking the complementary SOD-like functionality, and no examples of dual SOD/CAT dinuclear systems in water are known to date. $11,12$ 

Our results address the synthesis, solution, and solid state characterization of three novel  $Cu(II)$ -complexes, featuring a dinuclear copper-core stabilized by an  $N_3O$  donor ligand set (Scheme 1) and optimized for a combined superoxide dismutase and catalase-like activity in aqueous media, under physiological-like conditions. We show herein that the <span id="page-2-0"></span>stereoelectronic modulation of the  $Cu<sub>2</sub>$ -coordination sphere is instrumental to tune the mechanism and the antioxidant performance of the resulting complexes. Finally insights on the evolution of the active species are discussed.

#### ■ RESULTS AND DISCUSSION

Synthesis of Dinuclear Cu(II)-Complexes. The ligand HL<sup>1</sup> (2-{[[di(2-pyridyl)methyl](methyl)amino]methyl} phenol) has been used to provide a tetradentate  $N_3O$  donor set for Cu(II) binding with a bis-pyridyl, tertiary amine, and phenolate terminals. $^{7,13}$  $^{7,13}$  $^{7,13}$  $^{7,13}$  $^{7,13}$  Ligand modification has been addressed with the 2-fold aim of implementing (i) accessibility of the catalytic core by using a nonmethylated, secondary amine binding site (HL<sup>2</sup> = 2-({[di(2-pyridyl)methyl]amino}methyl)phenol); and (ii) a more electron-deficient copper-core by using p-nitrophenolate ligands  $(HL^3 = 2-(\frac{d}{d}(2-pyridy))$ -methyl]amino}methyl)-4-nitrophenol).<sup>[14](#page-9-0)</sup> In all cases, dimeric  $Cu<sub>2</sub>L<sup>x</sup><sub>2</sub>$  complexes have been obtained by reacting the proper ligand  $HL^x$  with copper perchlorate and triethylamine in alcoholic solvents under reflux conditions ([Scheme 1](#page-1-0)).<sup>7[,13](#page-9-0)</sup> Green crystals suitable for X-ray analysis have been isolated upon addition of acetonitrile  $(Cu_2L^1)$  or dimethylformamide  $(DMF)$   $(Cu_2L^2)$  and  $Cu_2L^3$  and cooling.<sup>14</sup>

**X-ray Analysis.** X-ray analysis of  $\text{Cu}_2\text{L}^x_2$  shows a  $C_i$  pointgroup symmetry for all three dinuclear complexes with a distorted octahedral geometry for the metal centers. Each  $Cu(II)$  atom is coordinated in a facial configuration by the three N atoms of the tetradentate ligand, while the phenolate ligands act as a bridge between the two metal centers. The metal coordination sphere is completed by a perchlorate ion in the  $\text{Cu}_2\text{L}^1_{2}$  structure and by a DMF molecule in the  $\text{Cu}_2\text{L}^2_{2}$ and  $\text{Cu}_2\text{L}^3$ <sub>2</sub> structures [\(Scheme 1](#page-1-0)). From the crystallographic structures, minor differences are observed in the  $Cu<sub>2</sub>O<sub>2</sub>$  core across the three complexes: the Cu−Cu distance ranges from 3.007 Å for  $Cu_2L_{2}^{1}$  to 3.033 Å for  $Cu_2L_{2}^{3}$  while the Cu–O– Cu angles slightly decrease, with values of  $100.2^{\circ}$  for  $\rm Cu_2L_2^1$ and 99.9° for  $Cu_2L_2^2$  and  $Cu_2L_2^3$ . The key feature observed moving from  $Cu_2L_2^1$  to  $Cu_2L_2^2$  or  $Cu_2L_2^3$ , both bearing a secondary amine on the equatorial copper position, is the different accessibility of the metal centers due to the Jahn− Teller distortion, which results in a relative strong coordination of a solvent molecule (DMF) for these two complexes. Indeed, solvent coordination induces a remarkable elongation of the Cu−N3 binding motif (binding with the apical pyridine) from a value of 2.327 Å in the  $\text{Cu}_2\text{L}^1$ <sub>2</sub> complex to 2.525 Å in the  $Cu<sub>2</sub>L<sup>2</sup><sub>2</sub>$  complex and 2.438 Å in the  $Cu<sub>2</sub>L<sup>3</sup><sub>2</sub>$  complex. This feature should impact on the substrate access to the copper active site and be relevant for catalysis (see structural parameters in the [Supporting Information](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)).

Spectroscopic and Solution Mass Characterization of the  $\textsf{Cu}_2\textsf{L}_2^{\textsf{x}}$  Complexes. The FT-IR spectra of the  $\textsf{Cu}_2\textsf{L}_2^{\textsf{x}}$ complexes confirm the ligand coordination mode, as the pyridines and phenol absorption bands are shifted toward higher frequencies upon metal binding and found at 1615− 1600 cm<sup>-1 (</sup>[Figures S11, S12, and S14](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)).<sup>15</sup> The retention of the dinuclear structure in solution is confirmed by ESI-MS, UV− vis, and EPR analysis. In all cases,  $ESI(+)$ -MS peaks are obtained for the expected molecular ions as formate or perchlorate adducts [\(Table S3,](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) formic acid was present in the eluent) with  $m/z = 779.0$   $[Cu_2L_2^1 + HCO_2]$ <sup>+</sup> and 833.0  $[Cu<sub>2</sub>L<sup>1</sup><sub>2</sub> + ClO<sub>4</sub>]$ <sup>+</sup> ([Figures S33 and S35\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf);  $m/z = 751.0$  $[Cu<sub>2</sub>L<sup>2</sup><sub>2</sub> + HCO<sub>2</sub>]<sup>+</sup>$  and 805.0  $[Cu<sub>2</sub>L<sup>2</sup><sub>2</sub> + ClO<sub>4</sub>]<sup>+</sup>$  [\(Figures S41](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)

[and S42](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)); and  $m/z = 841.2$   $[Cu<sub>2</sub>L<sup>3</sup><sub>2</sub> + HCO<sub>2</sub>]<sup>+</sup>$  and 895.1  $[Cu<sub>2</sub>L<sup>3</sup><sub>2</sub> + ClO<sub>4</sub>]<sup>+</sup>$  [\(Figures S43 and S44](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)).<sup>16</sup>

Similar UV-vis spectra are collected for  $Cu_2L_{2}^{1}$ ,  $Cu_2L_{2}^{2}$ , and  $Cu<sub>2</sub>L<sup>3</sup><sub>2</sub>$  (50–70  $\mu$ M) both in organic (CH<sub>3</sub>CN) and in aqueous phase (PBS 50 mM, pH 7.8) ([Figures S3, S7, and S8](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). In particular, the absorption maximum at about 265 nm is ascribed to the  $\pi - \pi^*$  transition of pyridines, while the phenolate ligand-to-metal charge transfer band is observed at higher wavelengths for  $Cu_2L_{2}^{1}$  at 410 nm (LMCT,  $\varepsilon = 1300$  $M^{-1}$  cm<sup>-1</sup>), for  $Cu_2L_{\frac{2}{3}}^2$  at 397 nm (LMCT,  $\varepsilon = 1700$  M<sup>-1</sup> cm<sup>-1</sup>), and for  $Cu<sub>2</sub>L<sup>3</sup><sub>2</sub>$  at 376 nm, overlapped with the absorption of the nitrophenol itself ( $\varepsilon = 23,000 \, \text{M}^{-1} \, \text{cm}^{-1}$ ) ([Figures S4, S6, and S8\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf).[17](#page-9-0) A d−d transition was also observed at 675 nm ( $\varepsilon = 280 \text{ M}^{-1} \text{ cm}^{-1}$ ) for  $\text{Cu}_2\text{L}^1$ , 668 nm ( $\varepsilon = 290$  $M^{-1}$  cm<sup>-1</sup>) for  $Cu_2L^2$  and 670 nm ( $\varepsilon = 170$   $M^{-1}$  cm<sup>-1</sup>) for  $Cu<sub>2</sub>L<sup>3</sup><sub>2</sub>$  ([Figures S4, S7, and S8](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). These spectral features are in agreement with phenol deprotonation upon binding.<sup>[18](#page-9-0)</sup> Moreover, the X-band EPR solution spectra are silent for all the complexes under investigation, thus confirming the stability of the dimeric core in aqueous phase (see further discussion, [Figure 4,](#page-6-0) and [Figure S76\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf).

Electrochemistry. The redox properties of  $Cu_2L_{2}^{x}$  (0.5– 1.0 mM) have been addressed by cyclic voltammetry (CV) experiments, performed both in acetonitrile and in aqueous solution (phosphate buffer, 50 mM, pH = 7.8). Under reductive scan in acetonitrile, one irreversible wave is attributed to the Cu<sub>2</sub><sup>II,II/I,I</sup> redox couple and observed at  $E_c$  =  $-136$  mV (vs NHE) for  $\text{Cu}_2\text{L}^1$ <sub>2</sub>, while two irreversible waves are observed for the  $Cu_2$ <sup>II,II/II,I</sup> and  $Cu_2$ <sup>II,I/I</sup>,I redox couples at  $E^1{}_c = -96$  mV and  $E^2{}_c = -465$  mV, and at  $E^1{}_c = 62$  mV and  $E^2{}_c$  $= -273$  mV (vs NHE), respectively, for  $Cu_2L^2$  and  $Cu_2L^3$ ([Figures S16, S22, and S28](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). In aqueous media the corresponding redox processes display quasireversible features observed at  $E_{1/2} = -161 \ (\Delta E_p = 350 \text{ mV})$ , -55 ( $\Delta E_p = 116$ mV), and 60 mV ( $\Delta E_p$  = 450 mV) (vs NHE), respectively, for  $\text{Cu}_2\text{L}^1_{2}$ ,  $\text{Cu}_2\text{L}^2_{2}$ , and  $\text{Cu}_2\text{L}^3_{2}$  species (see [Table 1](#page-1-0) and [Figures](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) [S17, S23, and S29](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). The observed  $\Delta E_p$  is likely ascribable to structural changes occurring for complex geometry upon oxidation and reduction of the copper-core. The increase of the potential values in the series indicates that the reduction of the copper-core is favored by less electron-donating ligands, that is, by replacing the tertiary amine in  $L<sup>1</sup>$  with a secondary amine in  $L^2$  and by introducing the nitro-substituted phenolate in  $L^3$ .

In the oxidative scan in acetonitrile, two irreversible waves are tentatively attributed to the  $Cu_2^{II,II} \rightarrow Cu_2^{III,II}$  and to the  $\text{Cu}_2^{\text{III,II}} \rightarrow \text{Cu}_2^{\text{III,III}}$  processes, observed at  $E^1_{a} = 1.06 \text{ V}$  and  $E^2_{a}$ = 1.38 V for  $\text{Cu}_2\text{L}^1$ <sub>2</sub> ([Figure S18](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)), and at  $E^1$ <sub>a</sub> = 1.28 V and  $E^2$ <sub>a</sub> = 1.62 V for  $Cu_2L^2$  [\(Figure S24](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). A single wave is instead obtained at  $E^1$ <sub>a</sub> = 1.56 V for  $Cu_2L^3$ <sub>2</sub> [\(Figure S30](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)).<sup>19</sup> In all cases, the addition of water yields the collapsing of the two anodic peaks into one single feature, observed at lower potential values [\(Figures S19, S25, and S31\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf). Therefore, in aqueous phase, the proposed oxidation of the copper-core,  $Cu<sub>2</sub><sup>II,II</sup> \rightarrow Cu<sub>2</sub><sup>III,III</sup>$ , gives rise to an irreversible single wave observed at  $E_a = 1.11$ , 1.07, and 1.31 V (vs NHE) for  $Cu_2L_{2,2}^{1}$  $\text{Cu}_2\text{L}^2$ <sub>2</sub>, and  $\text{Cu}_2\text{L}^3$ <sub>2</sub> [\(Table 1](#page-1-0), [Figures S20, S26, and S32](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)), likely implying a major structural change of the dinuclear complexes upon oxidation of the copper-core.<sup>[19,20](#page-9-0)</sup> As expected, the  $NO<sub>2</sub>$ -substituent effect in  $HL^3$  is responsible for the increase of the oxidation potential observed for  $\mathrm{Cu_2L^3_{2}}$ . In all cases, oxidation of the phenolate moiety of the ligand is observed above 1.6  $V<sup>21</sup>$  $V<sup>21</sup>$  $V<sup>21</sup>$ 

<span id="page-3-0"></span>SOD-like Activity. Metal-based artificial SODs are initially assessed on the basis of the thermodynamic driving force available for both the oxidation and the reduction of the superoxide anion. This is readily measured by considering the redox potential of the catalytic manifold. A favorable potential range lies between the potentials for  $O_2^{\bullet-}$  reduction to peroxide (0.89 V vs NHE, pH = 7) and its oxidation to  $O_2$  (−0.16 V vs NHE,  $pH = 7$ , with the optimal value, considering outersphere electron transfer, being at  $E = 0.36$  V (vs NHE).<sup>[5,](#page-8-0)[22](#page-9-0)</sup> Accordingly, all three complexes under investigation display the  $\text{Cu}_2^{\text{II},\text{II}/\text{I},\text{I}}$  redox couple within the SOD potential range, with  $\text{Cu}_2\text{L}^1_2$  set at the lower limit ([Table 1\)](#page-1-0), while the redox placement of  $Cu_2L^2$  and  $Cu_2L^3$  is shifted toward the envisaged optimum, at  $E = 0.36$  V vs NHE [\(Table 1\)](#page-1-0).

The SOD-like activity of  $\text{Cu}_2\text{L}^1_{2}$ ,  $\text{Cu}_2\text{L}^2_{2}$  and  $\text{Cu}_2\text{L}^3_{2}$  has been screened with the xanthine oxidase/cytochrome  $c$  (cyt  $c$ ) protocol to evaluate the  $O_2^{\bullet-}$  scavenging efficiency, by comparing the  $IC_{50}$  performance (i.e., the catalyst concentration to achieve the 50% inhibition of cyt c reduction, monitored at 550 nm in 0.05 M phosphate buffer, pH 7.8) and the related kinetic constant (log  $k_{\text{cat}}(O_2^{\bullet -})$ ) (see the [Supporting](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) [Information](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). $<sup>2</sup>$ </sup>

Inspection of [Table 1](#page-1-0) results indicates that all three dicopper complexes work as artificial SODs in phosphate buffer (pH 7.8) following a clear structure−reactivity trend where  $Cu_2L_2^1$  $\langle \text{Cu}_2 L_2^2 \rangle \langle \text{Cu}_2 L_2^3 \rangle$ . In particular a steady increase of the log  $k_{\text{cat}}(O_2^{•-})$  values is observed in the series, (respectively, 6.80, 7.27, and 7.55, [Table 1\)](#page-1-0) corresponding to a parallel decrease of the IC<sub>50</sub> concentration requirements, as low as 0.072  $\mu$ M for  $Cu<sub>2</sub>L<sup>3</sup><sub>2</sub>$ . This latter complex not only outperforms the related analogues but also stands as the most efficient Cu-based artificial SOD compared to either mono- or dinuclear literature benchmarks [\(Table 1\)](#page-1-0).<sup>[8](#page-8-0)−[10,24](#page-9-0)</sup> The superior SOD-activity of  $Cu<sub>2</sub>L<sup>3</sup><sub>2</sub>$  is likely ascribed to the interplay of both thermodynamic and kinetic factors, as the nitro-substituted ligand  $HL<sup>3</sup>$ improves the electron acceptor properties of the copper-core  $(E_{1/2} = 60 \text{ mV}$  vs NHE, [Table 1](#page-1-0)), while the secondary terminal amine can drive a favorable proton-coupled electron transfer (PCET) mechanism. In particular, the dependence of the SOD-like efficiency on the  $Cu^{II/I}$  redox couple suggests a copper-mediated mechanism where the stereoelectronic features of the  $N_3O$  ligand set can provide (i) a prompt evolution/stabilization of the  $Cu^{II/I}$  redox-manifold; (ii) an electrophilic and accessible recognition/binding site for  $O_2^{\bullet-}$ ; and (iii) proximal hydrogen bonding donors/acceptors to drive favorable PCET mechanisms and the stabilization of peroxide intermediates. $8-10,22,24$  $8-10,22,24$  $8-10,22,24$  $8-10,22,24$  $8-10,22,24$  While further studies are needed to clarify the role and impact of each effector to the catalytic activity, inspection of SOD performance suggests an innersphere dismutation reaction occurring at the single copper site (eqs 5 and 6).

$$

$$
 (6)

According to this hypothesis, the copper site can cycle between a five to six coordinate coordination geometry during SOD catalysis (see the discussion in the [X-ray Analysis](#page-2-0) section).

While catalytic dismutation of superoxide by  $Cu<sub>2</sub>L<sub>2</sub>$  is effective in the aqueous phase, oxidative degradation of the ligand dominates in  $CH<sub>3</sub>CN$  and DMF even at low temperature (up to  $-80$  °C), which hampers the detection of Cu-based superoxide and peroxide intermediates, generally characterized by distinct absorbance features at  $\lambda > 400$  nm ( $\varepsilon$  $= 10^3 - 10^4$ ).<sup>[25,26](#page-9-0)</sup>

CAT-like Activity. Copper-based artificial catalases, i.e., Cu-cores mimicking the inorganic cofactors of the natural catalases, are rare if compared with manganese or iron analogues.<sup>[2b,](#page-8-0)[10](#page-9-0)</sup> Expanding the copper role to  $\widetilde{H_2O_2}$  dismutation has the 2-fold aim of (i) implementing a dual SOD/CAT domino catalysis and (ii) understanding the stereoelectronic requirements to tune the reactivity at synthetic Cu-cores. This knowledge would stimulate new progress in the design of copper chelators that can revert the severe Cu-induced toxicity to a favorable and benign antioxidant effect.<sup>[27](#page-10-0)</sup>

Enzymatic  $H_2O_2$  dismutation involves a bielectronic process where both  $H_2O_2$  reduction to  $H_2O$  and oxidation to  $O_2$  are part of the catalytic turnover and occur with redox potential  $E_{(O_2/H_2O_2)}$  = +0.28 and  $E_{(H_2O_2/H_2O)}$  = +1.35 V (vs NHE, pH 7). In this scenario, the dicopper-core of  $Cu<sub>2</sub>L<sup>x</sup><sub>2</sub>$  is expected to cycle between the  $Cu_2^{III,III} \rightarrow Cu_2^{II,II}$  redox manifold, via a bielectronic process and redox potentials falling in the range  $E_{1/2}$  = 1.07–1.31 V (vs NHE, [Table 1](#page-1-0)).<sup>[2b](#page-8-0)</sup> The CAT activity of the  $\text{Cu}_2\text{L}_2^{\text{x}}$  was tested upon incubation with  $\text{H}_2\text{O}_2$  (30 mM) in aqueous borate buffer (BBS, pH= 7.8) at 25  $^{\circ}$ C by monitoring the  $O<sub>2</sub>$  production kinetics with pressure transducer equipment (Figure 1 and the [Supporting Information\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf). The artificial

Figure 1. Comparison of O<sub>2</sub> evolution kinetics by  $Cu_2L_{2}^{12}$ ,  $Cu_2L_{2}^{2}$ , and  $Cu_2L^3$  (200  $\mu$ M) upon incubation with H<sub>2</sub>O<sub>2</sub> (30 mM) in BBS  $(50 \text{ mM pH} = 7.8).$ 

catalase performance can be compared in terms of the  $O_2$ evolution rate  $(R_{\text{max}})$ , the resulting  $H_2O_2$  conversion (% yield), the turnover number (TON), and the second-order rate constant  $(k_{\rm H_2O_2}$   $\rm M^{-1}$   $\rm s^{-1})$  , determined under pseudo-first-order conditions, by varying the initial  $H_2O_2$  concentration ([Table 1](#page-1-0)) and the [Supporting Information](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)).<sup>[28](#page-10-0)</sup> While in all cases,  $O_2$ evolution levels off at ca. 35−40% yield (TON up to 60, [Table](#page-1-0) [1](#page-1-0)), a 5-fold rate acceleration is observed by  $Cu_2L^2$  and  $Cu_2L^3$ as compared to  $\text{Cu}_2\text{L}^1_{2}$ , with  $R_{\text{max}} = 4.4$ , 4.3, and 0.87  $\mu$ M O<sub>2</sub> s −1 , respectively ([Table 1\)](#page-1-0). Moreover, oxygen evolution by  $Cu<sub>2</sub>L<sup>1</sup><sub>2</sub>$  occurs with a definite lag-time (ca. 10 min), that is absent in both  $\text{Cu}_2\text{L}_2^2$  and  $\text{Cu}_2\text{L}_2^3$  catalytic profiles (Figure 1). Inspection of data in [Table 1](#page-1-0) shows that such a ligand effect is not directly ascribed to the  $\text{Cu}_2^{\text{III,III}} \rightarrow \text{Cu}_2^{\text{II,II}}$  redox potential and should be related to the more accessible and more flexible binding site of  $\rm Cu_2L^2_2$  and  $\rm Cu_2L^3_2$  lacking the steric hindrance

<span id="page-4-0"></span>of the methylated tertiary amine (see the X-ray discussion and [Supporting Information\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf).<sup>24</sup>

It is noteworthy that, for all catalysts, the final  $O<sub>2</sub>$  production yield is increased up to 75% based on  $H_2O_2$  conversion, TON = 110 ([Table 1](#page-1-0)), in the Krebs−Henseleit buffer (KH buffer, pH = 7.4, commonly used in perfused and superfused solution protocols), that contains a mixture of salts (sulfates, phosphates, carbonates, and chlorides) and glucose ([Figures](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) [S57 and S59\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf).<sup>[7](#page-8-0),[29](#page-10-0)</sup> However, in KH buffer, the  $O_2$  evolution kinetics displays a lag-phase of ca. 10 min for  $\text{Cu}_2\text{L}_2^2$  and  $\text{Cu}_2\text{L}^3$ <sub>2</sub>, up to 100 min for  $\text{Cu}_2\text{L}^1$ <sub>2</sub>, and lower rates up to 1.1  $\mu$ M O<sub>2</sub> s<sup>-1</sup> [\(Table 1\)](#page-1-0). This observation is consistent with possible inhibition by buffer anions (i.e., phosphate binding) that can slow down the overall process both in its initial phase and under turnover regime.<sup>30,3</sup>

Spectroscopic and Mechanistic Investigation of the **CAT-like Reactivity by Cu<sub>2</sub>L<sup>x</sup><sub>2</sub>.**  $H_2O_2$  dismutation by  $Cu_2L_2^x$ has been analyzed in more detail in order to address (i) the origin of the kinetic lag-phase, (ii) the evolution of the dicopper-core under the turnover regime, and (iii) the optimization of the catalytic efficiency. To this aim, timedependent UV−vis, EPR, and ESI-MS evidence has been collected in acetonitrile and/or in aqueous BBS. $^{32}$ 

In acetonitrile, under the conditions explored, the reference  $Cu<sub>2</sub> L<sup>1</sup><sub>2</sub>$  does not show any relevant CAT-activity, and no oxygen evolution is observed [\(Figure S61\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf). On the contrary, addition of  $H_2O_2$  (30 mM) to  $Cu_2L^1{}_2$  (200  $\mu$ M in CH<sub>3</sub>CN) causes a progressive modification of the UV−vis spectrum, with a decrease of the complex LMCT band at 410 nm, due to the Cu−phenolate interaction, and of the d−d bands at 675 nm, with the formation of three isosbestic points at 361, 475, and 612 nm (Figure 2a). This behavior is ascribed to a steady ligand degradation with bleaching of the copper-core features.

Indeed, ESI-MS analysis of the catalytic reaction shows a sharp decrease of the parent  $\rm Cu_2L_2^1$  signals with a parallel formation of few low intensity peaks with  $m/z$  between 700 and 800 ([Figures S34 and S62\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf). In aqueous phase, under oxygen evolution conditions (BBS, 50 mM, pH 7.8), the UV− vis spectra collected over time (Figure 2b) show an initial shift of the LMCT and of the d−d bands to lower wavelengths (<20 min) followed by their progressive fading, with no clear isosbestic points. This behavior points to a stepwise evolution of the dinuclear copper-core and of the ligand environment, via the formation of definite copper-based intermediates, upon reaction with  $H_2O_2$ . Time-lapse ESI(+)-MS analysis is instrumental to identify the copper complexes generated along the reaction progress (Scheme 2, [Figure 3](#page-5-0), and [Table](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) [S3](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). In particular, the parent  $Cu_2L_2^1$  (1), revealed at  $m/z =$ 751.0, 779.0, and 833.0 (see attribution in [Table S3\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf), is gradually converted to new dinuclear species (2), detected at a lower  $m/z$  ratio as a consequence of ligand oxidation, followed by the release of copper monomers (3), (Scheme 2, [Table](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) [S3](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)).<sup>26</sup> In particular, oxidation at the benzylic sites and cleavage of the resulting amidic bond are expected to yield ligand  $\text{L}^{\text{Ox}}$ and ligand  $L^{CI}$  (inset box of Scheme 2).<sup>[33](#page-10-0)</sup> The corresponding copper complexes are observed at  $m/z = 657.0$  and 384.0 attributed, respectively, to dinuclear  $[Cu<sub>2</sub>L<sup>Ox</sup>L<sup>C1</sup>(O)]<sup>+</sup>$  and to the monomer  $[\mathrm{CuL}^1(\mathrm{OH})]^+$ , formed in BBS solution, upon addition of  $H_2O_2$ , under oxygenic turnover (Scheme 2, [Table](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) [S3](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)).

Formation of monomers (3) shows a typical sigmoidal profile and levels off after ca. 150 min, at which point oxygen evolution slows down, and the reaction stops at ca. 40% yield.

**Figure 2.** UV-vis spectra over time of the reaction  $([\mathbf{Cu_2L}^1] = 200$  $\mu$ M,  $[H_2O_2] = 30$  mM) in (a) acetonitrile and (b) BBS 50 mM pH = 7.8 ( $t = 0$  min, before  $H_2O_2$  addition).

Scheme 2.  $ESI(+)$ -MS Mapping of  $Cu_2L_2^1$  Evolution in the Presence of  $H_2O_2$ , Showing Ligand Oxidation (Inset Box) and Formation of Inactive Cu Monomers ([Table S3\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)

According to this scheme, the dicopper-cores of 1 and 2 are both active catalysts and display similar CAT-like activity, as no depletion of the oxygen production rate is observed at <50 min, where 1 is substantially converted into 2, but 3 is still lagging behind. Along these lines, we can conclude that degradation of the dicopper-core of 1 and 2 to a single-site catalyst 3 is responsible for switching off  $H_2O_2$  dismutation at >50 min. The monomeric form 3 is likely unable to mediate a bielectronic mechanism, despite standing as a barrier to prevent the release of ligand-free copper ions and the formation of copper oxides/hydroxides known to induce the

<span id="page-5-0"></span>

Figure 3. (a)  $O_2$  evolution kinetics by  $Cu_2L_{2}^{1}$  (200  $\mu$ M) upon incubation with  $H_2O_2$  (30 mM) at 25 °C in BBS (50 mM pH = 7.8) with different concentration of NaBr. Catalyst evolution during the catalase cycle  $([\text{Cu}_2\text{L}_{2}^1] = 200 \ \mu\text{M}, [\text{H}_2\text{O}_2] = 30 \ \text{mM}$  in BBS 50 mM) monitored by  $ESI(+)$ -MS without (b) and in the presence of (c) [NaBr] = 50 mM where  $I_1$  is associated with  $[(1)]$  (751.0 m/z, 779.0  $m/z$ , 813.0  $m/z$ , and 833.0  $m/z$ ), I<sub>2</sub> to [(2)] (657.0  $m/z$  and 784.9  $m/z$ z), and  $I_3$  to  $[(3)]$  384.0 and 420.9  $m/z$ ) peaks intensity ([Table S3\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf). The relative amount of the specie  $(I_x/I_{tot})$  was measured as the ratio between the intensity of the peaks attributed to a species  $(I_r)$  over the total species amount  $(I_{\text{tot}} = I_1 + I_2 + I_3)$ . A similar behavior is obtained in the presence of NaBr, used as the scavenger of hydroxyl radicals (see further discussion), where additional peaks are observed at  $m/z =$ 784.9 and 420.9 attributed, respectively, to dinuclear  $\left[\mathrm{Cu_2L^1L^{Cl}} \right. +$  $2Br]^+$  and to the monomer  $[\mathrm{CuL^{Cl}+Br}]^+$ , [\(Scheme 2](#page-4-0), [Table S3\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf). In

#### Figure 3. continued

order to trace the role of the different copper-complexes formed during turnover regime, the kinetic profile associated with species 1− 3 ([Scheme 2](#page-4-0)) was monitored in BBS (50 mM, pH 7.8) by ESI(+)-MS analysis and compared with the  $O<sub>2</sub>$  evolution kinetics (this figure). Interestingly, the catalyst transformation follows a consecutive reaction scheme, where the dinuclear complexes, 2, originating from the pristine catalyst 1, build up to a maximum after ca. 50 min and are consumed to yield monomers 3 (part b).

peroxide decomposition via radical-type mechanisms.<sup>[34](#page-10-0)</sup> In order to inhibit possible Fenton-like radical reactions, NaBr was added at different concentrations, and the resulting oxygen evolution kinetics are reported in Figure 3a.<sup>[35](#page-10-0)</sup> The reaction was carried out in aqueous phase (BBS 50 mM, pH 7.8) with the same catalyst concentration  $(Cu_2L^1{}_2 = 200 \mu M)$  and NaBr in the range 10−200 mM (red, blue, and magenta curves in Figure 3a).

While there is no effect on the induction time of the reaction kinetics [\(Figure S64](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)), meaning that no radical processes are involved in the initial catalyst activation, a remarkable enhancement of the oxygen evolution rate is obtained by increasing the NaBr concentration, which leads up to a 90% yield of oxygen production and TON = 134 (Table 2 and

Table 2. Dependence of the Reaction Rate of  $O<sub>2</sub>$  Evolution by  $\text{Cu}_2\text{L}^1$ <sub>2</sub> (200  $\mu$ M) in the Presence of NaBr in BBS (50 mM, pH 7.8) and  $H_2O_2$  (30 mM)<sup>a</sup>

$[NaBr]$ (mM)	$R_{\text{max}} (\mu M O_2 s^{-1})$	<b>TON</b>	yield $(\%)$
0	0.87	52	35
10	1.4	87	58
50	2.5	122	80
200	3.1	134	90

 ${}^a$ Oxygen evolution kinetics monitored by a pressure transducer;  $R_{\text{max}}$ values were obtained by linear regression of data within  $10\%$   $H_2O_2$ conversion, and the estimated errors are within  $\pm 10\%$ ; yields based on  $H<sub>2</sub>O<sub>2</sub>$  conversion; slight overestimation of TON values might depend on the side reaction occurring between Br<sup>−</sup> and H<sub>2</sub>O<sub>2</sub> (see [Figure](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) [S63](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)).

Figure 3a). Control experiments confirm that a minor pathway of oxygen evolution occurs by a parallel process involving the copper-free NaBr/ $H_2O_2$  system [\(Figure S63](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). These observations indicate a prevalent CAT-like mechanism for  $O_2$ production, while a parallel route of hydrogen peroxide degradation via a radical process and ligand oxidation is limited to ca. 10%.<sup>[36](#page-10-0)</sup> These experiments may explain the increased performance registered in KH buffer, containing chloride and bicarbonate ions, likely serving as •OH radical scavengers ([Table 1](#page-1-0), [Figures S57 and S59\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf). $37$  To investigate the effect of NaBr (50 mM) on the catalyst fate and lifespan,  $ESI(+)$ -MS analysis was performed during the reaction progress (blue line kinetics in Figure 3a,c). In this case, the degradation of the pristine catalyst 1 is stopped for ca. 30 min and then proceeds forming dinuclear 2, and monomers 3 at a slower rate (compared in Figure 3b,c, see [Scheme 2](#page-4-0) and [Table](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) [S3](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) for  $ESI(+)$ -MS data).

The NaBr effect translates into a longer-lived resting state of the active catalytic manifold  $(1 + 2)$  that is maintained for >100 min, thus sustaining the oxygen production rate and leading up to ca. 90%  $H_2O_2$  conversion (Figure 3a, Table 2). In this scenario, the increase of rate and TON obtained in the <span id="page-6-0"></span>Scheme 3. Proposed Catalytic Cycle and Catalyst Evolution Occurring during  $H_2O_2$  Dismutation by  $Cu_2L_2^x$ 

 $a)$ 

presence of NaBr shows a saturation trend ([Figure S66\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf), and it is explained by an increased stability of the active catalyst, due to the switching off of radical side-reactions by added NaBr. The copper-catalyzed cycle for  $H_2O_2$  dismutation by 1 is proposed in Scheme 3, where (i) dinuclear 1 and 2 are the active catalysts, cycling between the  $\mathrm{Cu}_2^{\textrm{III,III}} \to \mathrm{Cu}_2^{\textrm{II,II}}$  redox states, and (ii) radical pathways are responsible for a parallel catalyst degradation route,  $1 \rightarrow 2 \rightarrow 3$ , that turns out to be mitigated by addition of bromide salts or in saline buffers as KH.

A similar NaBr effect has also been registered in the reactions catalyzed by  $\text{Cu}_2\text{L}^2$  and  $\text{Cu}_2\text{L}^3$  with oxygen evolution rates that increase steadily reaching a  $H_2O_2$ conversion >95% [\(Figures S67 and S68 and Table S4](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). ESI-MS analysis also confirms that  $\rm Cu_2L^2_2$  and  $\rm Cu_2L^3_2$  undergo a similar oxidative degradation when reacted with  $H_2O_2$ . Indeed, copper monomers are observed at  $m/z < 500$  that are ascribed to dimer dissociation and ligand oxidation at the benzylic methylene and at the secondary amine site ([Figures S45, S46,](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) [and S51 and Table S3\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf). $38$ 

The stepwise evolution of the dimeric copper-core under oxygenic turnover  $(1 \rightarrow 2 \rightarrow 3,$  Scheme 3) has been further addressed by X-band EPR analysis at 50 K. To this aim, the reaction solution, after addition of  $H_2O_2$ , was quenched under liquid nitrogen at definite time intervals, and EPR spectra were registered over time. Representative experiments preformed for  $\text{Cu}_2\text{L}^1$ <sub>2</sub> are reported in Figure 4, both in the absence and in the presence of the NaBr additive.<sup>39</sup>

Low-temperature EPR analysis is instrumental to investigate the magnetic properties of Cu(II)  $d^9$ -complexes, as a function of their coordination geometry, the symmetry of ligation, the bond distances, and the resulting Cu(II)−Cu(II) interactions. In particular, a significant modification of the EPR features is envisaged along the reaction progress, whereby the bis-μphenolate,  $Cu<sub>2</sub>O<sub>2</sub>$  core of 1 is expected to open up to a more open, mono- $\mu$ -phenolate dimer 2, and eventually leading to Cu(II) monomers 3.

In all cases, the starting dimers 1 turn out to be EPR silent (X band, 50 K; Figure 4 and [Figure S77](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)) which indicates a diamagnetic  $(S = 0)$  state, due to a strong antiferromagnetic coupling between the copper centers in the  $Cu<sub>2</sub>O<sub>2</sub>$ -core. Soon after the addition of  $H_2O_2$  (<10 min), the EPR spectra show the formation of a copper signal, that gradually evolves from an

 $b)$ 

Figure 4. (a) X-band EPR spectra at 50 K of  $Cu_2L_{2}^{1}$  (200  $\mu$ M) before and after the addition of  $H_2O_2$  (30 mM) in BBS (50 mM pH = 7.8). EPR analysis was performed on frozen aliquots of the reaction mixture, sampled at the indicated time. The monomer simulated spectrum is reported with a dashed line. (b) As above but with NaBr (50 mM), added before  $H_2O_2$ . The spectra are shown with their original intensity.

initial broad line shape to a narrow one typical of the monomeric copper complex (Figure 4a). An analogous trend is also registered in the presence of added bromide, albeit with a slower kinetics (Figure 4b). In both cases, the amount of paramagnetic species, calculated from the double integral of the spectra, steadily increases with time, confirming that the initial diamagnetic complex gradually breaks down into paramagnetic species.

The broad EPR signal, dominant at early stages, shows no resolved g and hyperfine tensor features and likely arises from a weak coupling between the two copper centers via dipole− dipole and exchange interactions. We ascribe this signature to a modification of the copper-core, where the spin−spin coupling is responsible for the broadening of the EPR features, but it is not strong enough to give rise to a triplet state  $(S = 1)$ , which is consistent with the formation of paramagnetic "loose" dimers.<sup>40</sup> The EPR signals appearing at longer time intervals ( $>50$  min) are typical of a monomeric  $S = 1/2$  copper species with an expected four-line pattern in the  $g_{\parallel}$  region consistent with hyperfine interaction with the Cu nucleus  $(I = 3/2)$ . The powder EPR spectrum of the monomer has been simulated with an axial g and A tensors ( $g_{\parallel} = 2.273$ ,  $g_{\perp} = 2.059$ ;  $A_{\parallel} = 500$ MHz,  $A_{\perp}$  = 5 MHz; [Figure 4a](#page-6-0), dashed line), using the Easyspin simulation program.<sup>[41](#page-10-0)</sup> The magnetic tensors are consistent with a distorted octahedral geometry imparted by the multidentate ligand environment. $42$ 

An analogous behavior is observed for  $\text{Cu}_2\text{L}^2_{2}$  and  $\text{Cu}_2\text{L}^3_{2}$ ([Figure S76\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf); therefore, the EPR analysis and the timeline of the registered spectral evolution complement the ESI-MS evidence, confirming the stepwise transformation of the pristine copper dimers, 1, under the turnover regime, that leads to "loose" dimers, 2, up to the catalytically inactive monomers, 3.We can thus propose the catalytic cycle reported in [Scheme 3](#page-6-0) that occurs along three reaction pathways where the copper dimers 1 and 2 are all active catalysts: namely,  $(i)$ the reductive half-reaction of  $H_2O_2$  dismutation in which the fully reduced Cu(II,II) is responsible for a two-electron/two proton transfer that cleaves the O−O bond and releases water, while being oxidized to the Cu(III,III) state; (ii) the oxidative half-reaction of  $H_2O_2$  dismutation in which the fully oxidized Cu(III,III)-core is responsible for a two-electron/two-proton oxidation, liberating  $O<sub>2</sub>$ , while restoring the reduced coppercore to close the catalytic cycle; and (iii) a Fenton-like radical mechanism that originates from the Cu(II,II)-core, by single electron transfer, that cleaves the O−O bond and generates the highly reactive •OH species. This latter pathway is responsible for ligand degradation eventually leading to the inactive copper monomers, 3.

In this scheme, the dismutation catalysis by the pristine dimers, 1, turns out to be the dominant pathway at the early reaction stage (<20 min) as indicated by ESI and EPR evidence on copper speciation [\(Figure 3](#page-5-0)b, black line; and [Figure 4a](#page-6-0)). At intermediate times  $($  < 100 min), the steady accumulation of dimers 2 in solution ([Figure 3b](#page-5-0), red-line; and [Figure 4](#page-6-0)a), resulting from the homolytic side-reaction, does not slow down the  $H_2O_2$  catalytic dismutation. This observation supports a bioinspired catalase mechanism, where the phenolate-bridged dimetal core serves as a "storage" station for electrons and protons used by the catalytic manifold, cycling between the Cu(II,II) and Cu(III,III) redox states.<sup>43</sup> Indeed, the catalytic dismutation of  $H_2O_2$  is switched off when copper monomers are prevalent at longer reaction times (>150 min) as indicated by the combined ESI and EPR evidence [\(Figure 3b](#page-5-0), blue line; and [Figure 4](#page-6-0)a). Furthermore, the increased activity and stability observed upon addition of a radical scavenger like bromide [\(Figures 3c](#page-5-0) and [4](#page-6-0)b) are explained by the suppression of monomer formation along the reaction progress (compare blue traces in [Figure](#page-5-0) [3](#page-5-0)b,c, and EPR signals a and b in [Figure 4](#page-6-0)). It is important to underline that, due to the high complexity of the process and

the presence of multiple side reactions, alternative or parallel pathways cannot be excluded.

In this scenario,  $H_2O_2$  coordination to one copper center, followed by the opening of one phenol bridge and the structural rearrangement of the complex, is likely responsible for the lag-phase especially evident in the oxygen evolution kinetics by  $\text{Cu}_2\text{L}^1_{2}$  leading to a structure similar to a recently reported di-Mn(II) catalase mimicry.<sup>[7a](#page-8-0)</sup>

To highlight the privileged CAT-like reactivity of the  $Cu<sub>2</sub>(II)$ -core, we have addressed the kinetic relevance of possible competitive pro-oxidant pathways triggered by  $H_2O_2$ . As a representative case, the antioxidant versus pro-oxidant capacity of  $Cu<sub>2</sub>L<sup>1</sup><sub>2</sub>$  has been evaluated by considering the catalytic bleaching of morin, generally used as the molecular probe for peroxidase screening [\(Scheme S1\)](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf).<sup>[44](#page-10-0)-[47](#page-10-0)</sup> The oxidative degradation of morin (0.12 mM) catalyzed by  $\text{Cu}_2\text{L}^1_2$  (50  $\mu$ M) in the presence of H<sub>2</sub>O<sub>2</sub> (10–30 mM in BBS buffer 50 mM, pH = 7.8, [Figures S78](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)−S80) is conveniently monitored via UV−vis spectroscopy, by registering the absorbance depletion at 390 nm over a time-range superimposable to the oxygen evolution kinetics. The rate of morin bleaching by  $\text{Cu}_2\text{L}_2^1$  varies linearly with  $\text{H}_2\text{O}_2$  concentration, yielding a second-order rate constants,  $k_b = 6.1 \times 10^{-4} \text{ M}^{-1} \text{ s}^{-1}$ , that is orders of magnitude lower than the  $k_{\text{H}_2O2}$  associated with the catalase-like activity of the copper complex (cf. [Table 1;](#page-1-0) and [Table S6 and Figure S80](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). The relative impact of the antioxidant versus the pro-oxidant performance of  $\overline{\text{Cu}}$   $_{2}\text{L}^1_{\phantom{2}2}$  can thus be evaluated on the basis of the so-called "protection" factor  $p = k_{\text{H}_2\text{O}_2}/k_{\text{b}}$ , calculated as the ratio between the rate constants associated, respectively, with  $H_2O_2$  dismutation and catalytic bleaching.<sup>[7a,](#page-8-0)[48](#page-10-0)</sup> As expected, the value of  $p = 377$ obtained for  $\text{Cu}_2\text{L}^1_2$  confirms the prominent  $\text{H}_2\text{O}_2$  dismutation activity by the dinuclear copper-core.<sup>[49](#page-10-0),[50](#page-11-0)</sup>

# ■ CONCLUSIONS

Our results showcase the first example of a dinuclear  $Cu(II)$ core exhibiting a dual SOD/CAT-like activity, in water under physiological pH. A tailored modification of the dinucleating ligand  $HL<sup>1</sup>$  has been instrumental to optimize kinetics and performance of both SOD and CAT manifolds. Other  $N_3O$ ligand sets in combination with copper were not reported to promote a dual antioxidant activity. $51$  In particular, peak activities (log  $k_{\text{cat}}(O_2^{e-}) = 7.55$  and  $k_{\text{H}_2\text{O}_2}$  up to 0.66 M<sup>-1</sup> s<sup>-1</sup>) are obtained with an HL ligand featuring a secondary amine and a p-nitrophenolate residue as key stereoelectronic effectors within the  $\text{Cu}_2\text{L}^3$ <sub>2</sub> coordination sphere.  $\text{Cu}_2\text{L}^3$ <sub>2</sub> stands as the most efficient and unique Cu<sub>2</sub>-based artificial SOD/CAT compared to literature benchmarks [\(Table 1](#page-1-0)). $8-10,24$  $8-10,24$  $8-10,24$  $8-10,24$  The resulting structure−reactivity trend  $\text{Cu}_2\text{L}^1_{\phantom{1}2}<\text{Cu}_2\text{L}^2_{\phantom{1}2}<\text{Cu}_2\text{L}^3_{\phantom{1}2}$ is supported by converging structural, electrochemical, and kinetics evidence, whereby the SOD and CAT manifold are, respectively, related to the  $\text{Cu}_2^{\text{II,II/II,I}}$  and  $\text{Cu}_2^{\text{III,III/II,I}}$  redox couples, mimicking the enzymatic mechanism. ESI-MS and EPR analysis of the time-dependent evolution of  $\mathrm{Cu_2L^x_2}$  under oxygen evolution turnovers confirms the active role of the  $Cu<sub>2</sub>$ core for  $H_2O_2$  dismutation, as monomeric fragments are found catalytically inactive. The prominent two-electron versus single-electron mechanism is also confirmed with radical scavenger probes, that turn out to favor the turnover efficiency, by depleting side ligand degradation pathways. While the peroxidase-like activity is often exhibited by artificial catalases,<sup>[45](#page-10-0)</sup> a high pro-oxidant activity is a potential risk factor <span id="page-8-0"></span>for the intrinsic stability of the artificial SOD/CAT complex, as the metal first coordination sphere represents a proximal oxidation target. In this scenario, the pro-oxidant activity of the Cu<sub>2</sub>-core is low compared to  $H_2O_2$  dismutation, yielding a high protection factor,  $p = 377$ . In conclusion, copper-based artificial SOD/CAT can offer a valuable alternative to iron and manganese analogues, while unveiling the impact of the coordination environment for contrasting copper toxicity.7,[22](#page-9-0)[,52](#page-11-0) Further studies will be directed to address the mechanistic scenario vis-à-vis the proposed reaction manifold ([Scheme 3](#page-6-0)).

(25) All attempts to isolate reduced mixed-valence species in the presence of superoxide and  $H_2O_2$ , either in organic solvent or in water media, were not successful even at low temperature (up to −80 °C). Moreover, the reaction between the ligand precursor and  $Cu(I)$  salts, even under  $N_2$  atmosphere, leads to fast ligand degradation and to the deposition of metallic copper.

(28) The rate of oxygen production with  $Cu_2L_2^1$  shows saturation behavior amenable with the Michaelis−Menten equation ([Figure](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf) [S69](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). However, the large excess of  $H_2O_2$  required (>60 mM) leads to degradation of the complex [\(Figures S70](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)−S74), releasing copper and leading to the formation of copper hydroxide and oxides. For this reason, the Michaelis−Menten constants cannot be extrapolated.

(48) The protection factor  $p$  was calculated as the ratio between  $k_{\text{H}_2\text{O}_2}/k_\text{b}$  obtained by the reported  $p = k_\text{cat}/(K_\text{M}k_\text{b})$  equation where  $k_{\text{cat}}/K_{\text{M}} = k_{\text{H}_2\text{O}_2}.$ 

(49) UV−vis monitoring of morin bleaching by the best performing  $Cu<sub>2</sub>L<sup>3</sup><sub>2</sub>$  is hampered by spectral overlap; however, similar  $p$  factors can be expected considering the enhanced  $k_{\mathrm{H}_2\mathrm{O}_2}$  and TON values leveling off at ca. 40%  $O_2$  yield [\(Table 1](#page-1-0), [Figure 1](#page-3-0)), thus indicating a similar balance between catalase-like activity (antioxidant) and catalytic ligand oxidation (pro-oxidant).

<span id="page-11-0"></span>(50) For the sake of comparison, the reference mononuclear copper complex, Cu(PBMPA), is characterized by a  $p\approx 10^{-4}$ , thus showing a reversed antioxidant response (cf. [Table 1](#page-1-0) and [Table S6](http://pubs.acs.org/doi/suppl/10.1021/acscatal.0c01955/suppl_file/cs0c01955_si_001.pdf)). The low p value might arise from prevailing single-electron transfer mechanisms, with the formation of radical species.
